# Modern "Lit" Exchanges

- Fully automated, transparent, real-time order book
- Continuous double auction between buyers/sellers
- Replacing manual/floor exchanges, specialists, etc.
- Many advantages and applications:
  - *transparency*
  - data-driven algorithmic trading
  - estimating market impact
- *Major disadvantage:* executing very large orders
  - distributing over time and venues insufficient
  - many buy-side parties are "compelled"
- Thus the advent of... *Dark Pools*
  - specify side and volume only
  - no price specified, execution by time priority
  - price generally pegged to light midpoint
  - not seeking price *improvement*, just execution
  - *only learn (partial) fill for your order*

By SARAH N. LYNCH

WASHINGTON -- The Securities and Exchange Commission unanimously agreed Wednesday to consider three proposals aimed at shedding more light on non-public electronic trading entities including dark pools, which match big stock orders privately.

The proposals would require dark pools to make information about an investor's interest in buying or selling a stock available to the public instead of only sharing it with a select group operating with a dark pool. They would also require dark pools to publicly identify if their pool executes a trade.

"We should never underestimate or take for granted the wide spectrum of benefits that come from transparency," SEC Chairman Mary Schapiro said. "Transparency plays a vital role in promoting public confidence in the honesty and integrity of financial markets."

Dark pools, a type of alternative trading system that doesn't display quotes to the public, are just one part of a broader probe the SEC is conducting into market structures. Recently, the SEC also voted to consider banning flash orders, which let some traders get a sneak peek at market activity. The agency is also looking into other areas

# The Dark Pool (Allocation) Problem

- Given a sequence or distribution of “client” or parent orders, how should we distribute the desired volumes over a large number of dark pools?
  - a.k.a. Smart Order Routing (SOR), dispersion, etc.
- May initially know little about relative quality/properties of pools
  - may be specific to stock, volatility, volume,...
  - ...a *learning* problem
- To simplify things, will generally assume:
  - client orders all on one side (e.g. selling)
  - client orders come i.i.d. from a fixed distribution
    - ...even though our “child” submissions to pools will not be i.i.d.
  - statistical properties of a given pool are static
- All can be relaxed in various ways
- Main contributions:
  - a theoretical framework, algorithm and analysis
  - some empirical validation

# Theoretical Framework and Algorithm

# Modeling Available Volume: Single Venue

- $v$  shares submitted
- draw  $s \sim P$
- execute  $\min(v, s)$
- *censored* observations

# Multiple Venues

Client volume  $V$   
( $V \sim \text{dist. } Q$ )

$v_1$  shares

$v_2$  shares

$v_3$  shares

$v_4$  shares

Venue 1

Venue 2

Venue 3

Venue 4

*Allocate...*  
*...How?*

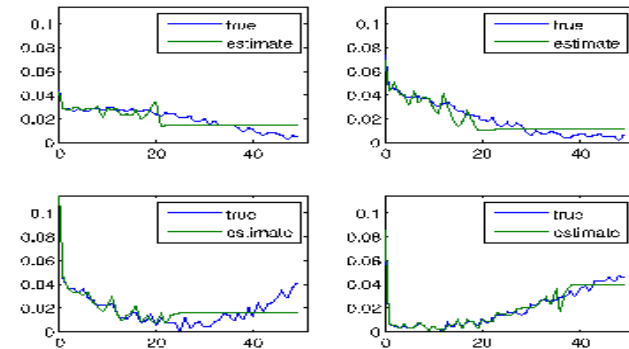

## Two Subproblems

- Optimal allocation under known distributions:
  - greedy algorithm for one-step max fill; other objectives
- Estimating distributions from censored data:
  - *Kaplan-Meier* is MLE; need new convergence analysis/rate

# The Learning Algorithm

- Initially know *nothing* about the venue distributions
  - must simply start allocating each client order
- For each venue, observe (partial) executions
- From censored data, estimate each distribution
  - using an *"optimistic"* Kaplan-Meier estimator
- From distribution estimates, compute next allocations
  - using *greedy allocation* on estimates
- Note: our allocations strongly influence observations
  - exploration-exploitation* trade-off

- Main claim: simple allocate/re-estimate loop *rapidly converges to near-optimal allocations*
  - exploration is *implicit*: always optimizing w.r.t. current estimates
  - may or may not "fully" learn/explore distributions

# Sketch of Analysis

- Algorithm:
  - initialize estimated distributions  $P'_1, P'_2, \dots, P'_k$
  - repeat:
    - compute greedy optimal allocations to each venue given the  $P'_i$
    - use censored data to re-estimate  $P'_i$  using *optimistic* K-M
- Analysis:
  - Define "known prefix"  $c[i]$  for each  $P[i]$
  - if allocation to *every* venue  $i$  is  $< c[i]$ , already near-optimal
    - know "enough" about the  $P_i$  to make this allocation ("exploit")
  - if for some venue  $j$ , submitted volume  $> c[j]$ , we "explore"
    - so eventually  $c[j]$  will increase  $\rightarrow$  improve  $P'_j$
  - *optimistic K-M*: tail modification ensures always exploit/explore
- *Main Theorem: algorithm efficiently converges to near-optimal*
  - non-parametric and parametric versions

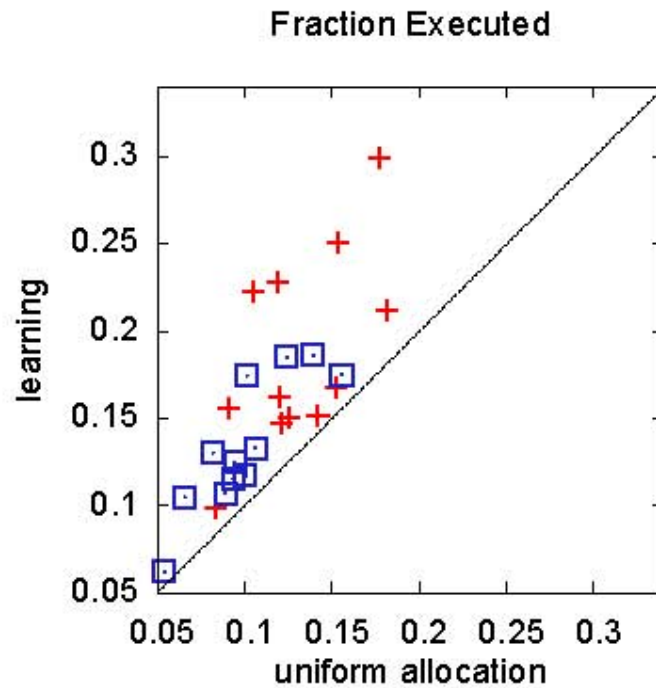

# Some Empirical Validation

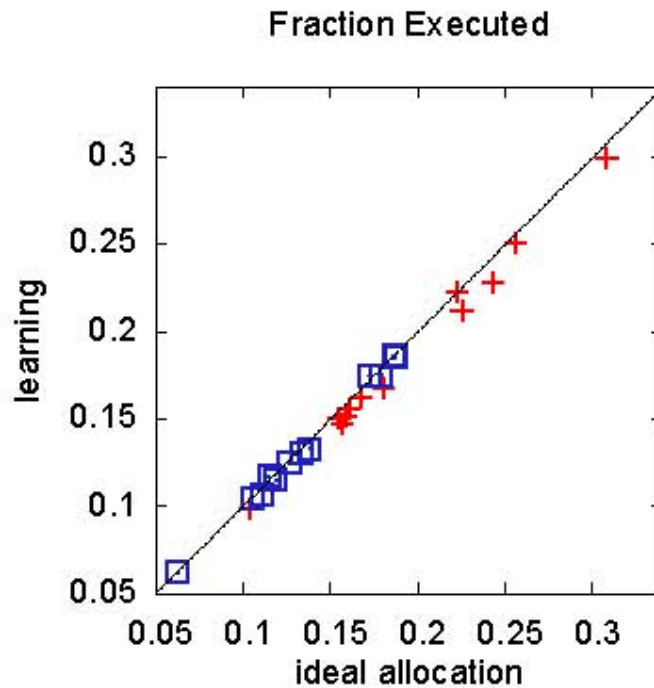

# Experimental Framework

- *The Data:*
  - submissions and fills for 12 liquid names x 4 dark pools = 48 pairs
  - proprietary trading flow of large brokerage (internal "clients")
  - pools: BIDS, AUTO, DE Shaw, NYFIX
  - ~1200 orders, ~1.3M shares per name/pool pair (30-day period)
  - ~16% partial executions, ~9% filled by volume, ~11% censored
  - data cannot be directly used to evaluate algorithms/policies
  - instead use data to build a *parametric simulation* framework
- *The Players:*
  - our allocate/re-estimate algorithm
  - a "bandit"-style allocation algorithm
    - simple weight per venue;
    - multiplicative updates on partial/no fill bit
  - uniform allocation (non-adaptive strawman)
  - ideal allocation with known distributions (unrealizable in practice)

# Our Algorithm vs. Uniform Allocation

# Our Algorithm vs. Ideal Allocation

# Conclusions

- Nice no-regret follow-up: Agarwal, Bartlett, Dama
- Other censored trading problems
- Solution for basic dispersion problem; better to condition:
  - targeted volume
  - targeted horizon
  - lit book pressure, buy/sell imbalance, spread,...
